.**Abstract:**
The advantage of Mobile Ad-hoc Networks (MANETs) is to form a wireless network in the absence of fixed infrastructure. Early stages of routing protocols of MANETs were, incapable of handling security issues but by the introduction of newer techniques like cryptographic techniques enabled them to handle the routing information securely. The present paper details the newly proposed SAODV and TAODV and further compares the same with the existing MANET routing protocols.

Key words:- Mobility, Ad-hoc, Security, Routing, Cryptography, Trust-based, Performance

.1.Introduction

In traditional wireless networks, a base station or access point facilitate communications between nodes with in the network and communications with destinations outside the network. In contrast, MANETs forms a network in the absence of fixed infrastructures. The requirement of these networks is only nodes that can interact with radio hard wares so as to route the traffic using the routing protocol. Thus the reduced essential requirement s of such networks, along with their adoptability into tiny resource-limited devices made them more popular and is much preferred for several applications in the area of communications.

Routing protocols determines the nature of data forwardness as well as its adaptability to topology changes that results by mobility. Initial MANET routing protocol like AODV [18], was not designed to withstand malicious nodes within the network or outside attackers near by with malicious intent. Subsequent protocols and protocol extensions have been proposed to address the issue of security [1,2,8,14,20,24,25,26]. Many of these protocols seek to apply cryptographic methods to the existing protocols in order to secure the information in the routing packets. This attack is very effective in MANETs as the devices often have limited battery power in addition to the limited computational power.

The trade-off between strong cryptographic security and DOS (Denial of service) has become increasingly important as MANET applications are developed which require a protocol with reasonable security and reasonable resistance to DOS, a kind of middle-ground. It has been suggested that various trust mechanisms could be used to develop new protocols with unique security assurances at different levels in this trade-off [5,27]. However, the arguments for this have been purely theoretical or simulation-based. Determining the actual span of this trade-off in real world implementations is of utmost importance in directing future research and protocol design.

In this paper considers two proposed protocol extensions to secure MANET routing. The first, SAODV [25], uses cryptographic methods to secure the routing information in the AODV protocol. The second, TAODV [15], uses trust metrics to allow for better routing decisions and penalize uncooperative nodes. While some applications may be able to accept SAODV's vulnerability to DoS or TAODV's preventative security, most will require an intermediate protocol tailored to the specific point on the DoS/security trade-off that fits the application. The tailored protocols for these applications will also require performance that falls between that of SAODV and TAODV. Understanding how the SAODV and TAODV protocols (which are on the boundaries of the DoS/security trade-off) perform on real hardware, and to what extent there exists a performance gap is a prerequisite for being able to develop the intermediate protocols. Such evaluation is not only required for developing intermediate protocols, but also for determining the direction for development of new trust metrics for ad-hoc networks. In this paper we provide the first performance evaluations for these protocols on real world hardware.

2. Related work

Several different protocols have been proposed for ad-hoc routing. The earliest protocols such as DSDV [19], DSR [11], and AODV [18] focused on problems that mobility presented to the accurate determination of routing information. DSDV is a proactive protocol requiring periodic updates of all the routing information. In contrast, DSR and AODV are reactive protocols, only used when new destinations are sought, a route breaks, or a route is

no longer in use. As more applications were developed to take advantage of the unique properties of ad-hoc networks, it soon became obvious that security of routing information was an issue not addressed in the existing protocols. In [13], Lundberg presents several potential problems including node compromise, computational overload attacks, energy consumption attacks, and black hole attacks. Deng et al. further discuss energy consumption and black hole attacks along with impersonation and routing information disclosure in [3]. Jakobsson et al. categorize attacks as manipulation of routing information and exhaustive power consumption, and provide detailed treatments of many characteristic attacks in [10].

While research has focused on "lightweight" security mechanisms, some proposed protocols use more expensive asymmetric cryptography. In [26], Zhou and Haas present a multi-path protocol extension that uses threshold cryptography to implement the key management system. It requires some nodes to function as servers and an authority to initialize these servers. Zapata and Asokan propose SAODV [25], a secure version of AODV, which uses digital signatures and hash chains to secure the routing messages.

In [22], Pissinou et al. propose a trust-based version of AODV using static trust levels. The same authors then extend this protocol in [7] to thwart multiple colluding nodes. Neither of these adress securing the trust exchanges, or the overhead involved. Li et al.introduce a trust-based variant of AODV in [12] that secures the trust information. However, their protocol requires an intrusion detection system in the network. Finally, Meka et al. propose a third trusted AODV with a simple method of evaluating trust even without source routing [15].

Our work in this paper considers the asymmetric cryptography and trust-based extensions to AODV presented in [25] and [15] respectively and shows a real world comparison of the performance of the two protocols. Our results suggest that new protocols can be developed which take advantage of the best features of both types of protocols, and which share aspects of each security model.

3. Implementation

In order to get an understanding for the real world performance of the AODV, SAODV, and TAODV protocols, we have implemented each of them on real hardware and measured their performance. In this section we detail the setup for the experiments used to acquire these measurements. We first describe the supporting hardware and software setup for our implementations. We then present details on the actual implementation for each of the three protocols. Finally we detail the design of

the experiments used to evaluate the protocols and explain why these tests are more relevant than other more common metrics.

Our AODV implementation is the result of previous paper in this area. The implementation is designed to run on the Linux/windows x operating system. As with many other AODV implementations for Linux/winX, it separates functionality into a kernel module and a user space daemon. The kernel module uses hooks in the net filter interface to send packet headers from the wireless interface to the user space daemon. The daemon then determines how to handle the packet. If the packet is a routing control packet, then the daemon processes the packet in accordance with the AODV specification. If instead the packet is a data packet, the daemon determines whether or not a route exists to the necessary destination. If there is a suitable route, the packet is flagged and the kernel module queues it to be sent out. If no route exists, the daemon begins route discovery. Once a route is found, the daemon enters the route into the kernels routing table. It then flags the packet (and any additional packets arriving during discovery) to be queued for transmission. The implementation is written completely in Java

Table 1   : Network setup for round trip timings

In order to implement SAODV, it was necessary to have a library of cryptographic operations. We used Open SSL for this purpose, and we developed a security library which wrapped much of Open SSL's functionality into components appropriate for ad-hoc routing purposes. One particularly useful feature of the security library is that it allows easy use of several different OpenSSL contexts at once. For SAODV, this was useful as nodes must switch between signing, verifying, and hash chain operations rapidly to both send and receive routing messages. New data structures were added for SAODV's single signature extension and the necessary code was added to the message processing functions for RREQ, RREP, HELLO, and RERR messages.   The design of the AODV implementation allowed SAODV functionality to be implemented while maintaining one binary with the ability to run both protocols.
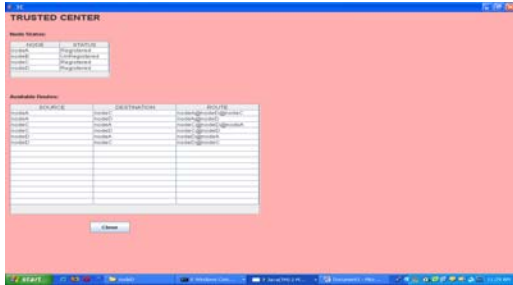

Fig 2: Trusted center for Both the protocols

Fig 3: Using the TAODV send the message

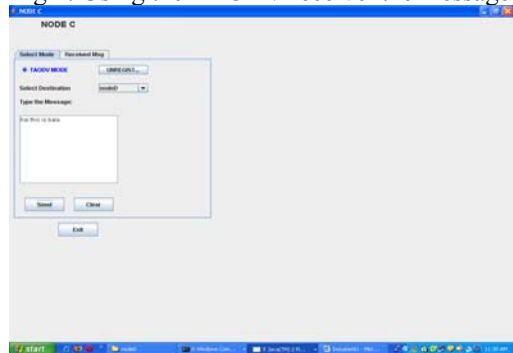

Fig 4: Using the TAODV receive the message

Fig 5: Using the SAODV send the message

Fig 5: Using the SAODV receive the message

Implementing TAODV required many additions similar to those involved in SAODV. New data structures were used for the NTT as well as the extended messages and the new R ACK message. Similarly, message handling functions were updated to use the extensions and take the appropriate actions. One challenge in implementing TAODV was counting packets sent, forwarded, or received for a particular route. While it intuitively seems to be something that should be implemented in the kernel module that is already tied into the net filter framework, this would require extra data exchange between the kernel module and the daemon. Since our implementation already passes packet headers to the daemon for route discovery initiation and flagging, it was simply necessary to place the counting mechanism in the daemon.

Keeping track of the additional routing information required significant extension of our AODV implementation. The original implementation does not support any multi-path entries in the routing table. Modifying it to support such a setup for TAODV would have required rewriting significant amounts of the base AODV code. Instead, we implemented a multi-path capable routing table for use exclusively by the TAODV protocol. When a node initially discovers a route, or changes the active route to a particular destination, it merely copies the necessary entry to the daemon's local routing table and marks it as having been altered so that it is updated in the kernel's routing table at the next sync. This simplified the implementation using only a negligible amount of extra memory.

3.1 Testing

There were two performance factors we were interested in for the purposes of this comparison. The first is the per-packet processing overhead. It is important to note that only CPU time was measured. Therefore this overhead reflects use of the processor by each protocol. In these tests we use AODV as a baseline. Thus, for SAODV we measure the time it takes to generate an SSE for RREQ, RREP, and HELLO messages. We also measure the time it takes for a node to verify an SSE for those same messages. For TAODV we measure how long it takes a node to generate or process and update RREP and R ACK messages. Due to the fact that some of the operations we measure have a runtime less than the resolution of our timer (5ms as per the Linux kernel), we perform a large number of operations back-to-back per measurement. We then make multiple measurements.

Operation	Processing Time(ms)	Std.Devation
SSE Generation	25.8	0.18
SSE Validation	2.6	0.06

Our second performance metric is round trip time for route discovery. The justification for this metric lies in the fact that we are looking at securing the routing control packets. Once a route is established, data is forwarded with the same efficiency regardless of the routing protocol. Therefore, it is important to see how the per-packet overhead along with the increased packet size affect the time for route discovery. For this test, we measure the performance of AODV in addition to that of SAODV and TAODV. This is necessary because both AODV and TAODV will generate RREPs after fewer hops when the destination's neighbor responds, while SAODV requires that the destination itself responds. For our experiments, we used a five node network consisting of one laptop and four Zauruses as illustrated in Figure 1. We used the network sniffer ethereal [6] running on the laptop to measure the time elapsed from the sending of the RREQ to the receipt of the RREP.

4. RESULTS

For the per-packet overhead tests, we measured the amount of processing time a node spends above and beyond that required for conventional AODV. All tests were performed on the Zauruses with only the necessary software running (i.e., no graphical login manager, no X server, etc.). In the SAODV tests, we measure generation and validation of the SSE which requires hash computation and a digital signature/verification. The hash function used for these tests was MD5 and the digital signature/verification was performed using a 256-bit RSA key pair. There were 1000 operations run per measurement and 1000 measurements overall. Table 1shows the results of our SAODV tests.

Consequently, in order to send a RREQ, RREP, or HELLO message, the node spends 30.8 milliseconds generating the SSE. The significant impact on performance occurs in generating the SSE for HELLO messages since they are sent periodically. According the to AODV specification, a node should send a HELLO message every HELLO INTERVAL milliseconds unless it has broadcast any messages during the previous interval. This means that only RREQ and RERR messages could prevent sending a HELLO message, as all other messages are

unicast. Obviously, this can place a significant burden on each node.

Operation	Processing Time	Std.Devation
RReq/Hello Send	0.354	0.019
RReq/ Hello Processing	0.3545	0.019
R Ack Send	0.193	0.003
RAck Proces	0.210	0.004

Table 2 TAODV Per Packet Overhead Time

Since SAODV requires that each message with a SSE is validated before any further processing takes place, each RREQ and RREP gets delayed 3.8 milliseconds at each hop which forwards it. In addition,HELLO messages take the same amount of time to be validated. While nodes are supposed to let ALLOWED HELLO LOSS * HELLO INTERVAL milliseconds pass before deciding a link is broken and a neighbor should be removed from its routing table, it is conceivable that on a node with several neighbors and a large amount of data to forward, route status may fluctuate for some neighbors whose HELLO packets get delayed in validation.

In TAODV, we measure the per-packet overhead for RREP, HELLO, and R ACK messages. The system-wide parameters discussed in [15] do not influence the overhead of TAODV for any of the tests we performed. However, it was necessary to fix these values to allow for the calculation of RSV. For all TAODV tests we used the following system-wide parameter values: i = 0.8, p= 0.6, ph = 0.4, pc = 0.2, $\alpha1$= 0.4, $\alpha2$= 0.4, and $\alpha3$= 0.2. Due to the very small running time of the operations, one million operations were performed per measurement and 5000 measurements were taken. Table 2 shows the results for the TAODV tests.
As the results show, there is much less per-packet overhead for TAODV when compared to SAODV. The main source of overhead involved the R ACK packets. Since the R ACK packets are new packets rather than packet extensions, it was necessary to allocate a packet buffer in the message sending system of our implementation each time a R ACK packet was to be sent. With other messages that were extended, the packet buffer was already allocated and the extension was simply written into free space at the end. This difference contributed significantly to the 0.193ms overhead for sending the R ACK message.
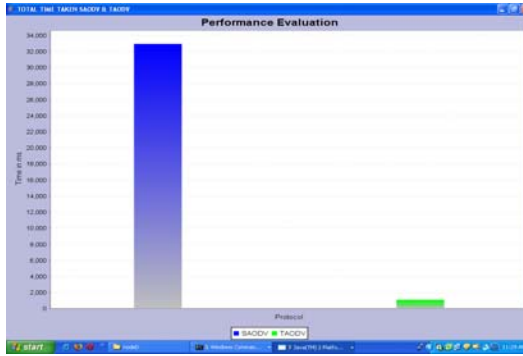

Table 4: Performace of SAODV

Table 5: Comparison of SAODV & TAODV

The overhead for processing the R ACK message was almost completely due to the recalculation of the OTV and RSV values. The TAODV implementation used double primitives for all calculations in order to keep with the protocol description in [15].

4.1 Comparison results

The round trip tests for route discovery were performed for all three protocols. This was particularly important due to the differences in which node sends the RREP as described in Section 4.1. Due to the nature of the measurements, only one route discovery operation could be executed per measurement. Overall 5000 of these individual measurements were performed. Table 3 shows the results of the tests.

Protocol	Round Trip time	Std.Deviation
AODV	138.772	0.765
SAODV	124.341	0.543
TAODV	172.553	0.832

Table 3 Round Trip Time
These results show that SAODV is indeed a significantly more expensive protocol. Specifically, SAODV takes 2.35 times as long as conventional AODV to get a RREP back to a RREQ originator. This is due, in part, to the added cryptography and increased message size. This is also due to the inability of intermediate nodes to respond to RREQs. Traversing the additional hop in both directions adds to the latency.

The results also show that the use of SAODV will require adjustments to the recommendations for configurable parameters in AODV. This is missing from the current draft standard for SAODV. For example, the current suggested NODE TRAVERSAL TIME   is 40ms which results in NET TRAVERSAL TIME being set to 1400ms. The value of NET TRAVERSAL TIME serves as the timeout for RREQ messages. Consequently, as per the results above, if these parameters were not adjusted, nodes would have problems discovering routes of length greater than ten hops.

In some applications this may not cause problems. However, in certain applications such as large area sensor networks, routes of this length or greater would not be unreasonable to expect. TAODV, on the other hand, takes only 1.11 times as long as AODV. This shows that the trust-based calculations and additional information exchange can be used without incurring the overhead of SAODV. While there is some expense for the trust calculations, it is not nearly as expensive as the cryptographic operations. The results show that TAODV is indeed at the opposite end of the trade-off from SAODV. This is due to the fact that the TAODV information itself in each packet is not secured.

Overall, the results show that there is indeed a wide spectrum in the tradeoff between cryptographic security and DoS. By adding an appropriate lightweight security mechanism to secure the trust information in the routing packets, a hybrid protocol can be created which is less expensive than SAODV and more secure than TAODV. Future

protocol designs should seek to use various new combinations of smarter, trust-based metrics and lightweight security mechanisms in order to develop hybrid protocols across this spectrum

5. Conclusions

In this paper, we have compared the SAODV and TAODV protocols for securing ad-hoc network routing. We presented the results of implementation and evaluation of both protocols. The expected difference between the two protocols was shown to be consistent with this real world scenario. These experiments showed that there is significant room between the two protocols for a secure hybrid protocol to be developed which takes advantage of the strongest points of both.
